Abstract: Endothermic hydrocarbon fuels undergo thermal cracking before entering the combustion chamber and can produce a mixture of unreacted fuels and pyrolysis products (i.e. cracked fuels). The objective of this work is to investigate the effects of pyrolysis conversions, pyrolysis pressures, ignition pressures and free radicals on ignition characteristics of cracked *n*-decane over temperature of 1300–1800 K, pressure of 0.1–3.0 MPa and equivalence ratio of 1.0. Components of the thermally cracked *n*-decane at 3.0 and 5.0 MPa in a flow reactor were calculated theoretically using an accurately combined mechanism, which are in good agreement with the experimental results in literature. The results showed the conversion rates of *n*-decane cracking at 3 and 5 MPa are 46.2% and 58.8%, respectively. The distribution of cracking products is consistent, but the ethylene content decreases with the increase of pressure, while the alkane content increases with the increase of pressure. Meanwhile, the content of free radicals at 3 MPa is slightly higher than that at 5 MPa, but the content of free radicals is very low. Ignition delay time increases with the decreasing of *n*-decane conversion and pyrolysis pressure, while higher ignition pressure can shorten it significantly. Furthermore, the presence of free radicals in cracked *n*-decane could accelerate the ignition process with ignition delay time shortening more than 15% when the conversion was less than 40%, compared with that of cracked *n*-decane without radicals.

Key words: ignition delay time; cracked fuels; *n*-decane; free radicals; sensitivity analysis

1 Introduction

Endothermic hydrocarbon fuels are proposed as one of the key candidates to solve the thermal management problems in advanced aircrafts, due to their excellent endothermic capacities and capacities to provide extra heat sinks by decomposition reactions^[1–3]. In advanced aircraft engines, fuels will undergo thermal cracking in heat exchanger prior to combustor, producing a mixture of smaller hydrocarbons, hydrogen and a small amount of free radicals

(e.g. methyl, ethyl, allyl). Then the mixture of cracking products (including radicals) and unreacted fuels that is marked as cracked fuel undergoes the combustion in the combustor^[4–6]. Therefore, it is significant to study the ignition characteristics of cracked fuel to design and improve the engine in advanced aircraft.

Nowadays, the researches in literature mainly focus on the measurement of the ignition delay time of single or binary fuels, while the reports on the ignition delay time of cracked fuel are relatively few. Puri et al.^[7] theoretically studied ignition delay time of two different components of cracked JP-7 by different kinetic models, concluding that the addition of C3 species could reduce the ignition delay time with a limit. Colket and Spadaccini^[4] conducted shock tube experiments to investigate the effect of cracking on ignitability over the range of temperature of 1201–1455 K, equivalence ratio of 0.5–1.0,

and pressure of 0.7 MPa. $0.3\text{CH}_4/0.6\text{C}_2\text{H}_4/0.1\text{C}_7\text{H}_{16}$ (baseline-fuel) was chosen as the surrogate of cracked products, with addition of heptane into baseline-fuel to simulate low conversion (80% C_7H_{16}) and addition of hydrogen for dehydrogenation (10% H_2). They concluded that all these mixtures ignited more easily than heptane at present experiments. In addition, addition of heptane increased ignition delay time while addition of hydrogen decreased it but with small amount. Castaldi et al.^[8] studied theoretically about how pyrolysis influenced on ignition delay time of JP-8 at stoichiometric ratios, based on calculated pyrolysis products which contained 17 pyrolysis product components and 35% unreacted fuels. Ignition delay time calculations of three modified fuels (propene converted to propane, toluene to methylcyclohexane, methane to ethane and hydrogen) were compared with JP-8 at 1000 K and 0.1–0.3 MPa. They found that pyrolysis products ignited faster than JP-8 at 0.1 MPa while slower than JP-8 at 0.3 MPa. The process of re-hydrogenating the unsaturated products would inhibit ignition, while methane converting to ethylene and hydrogen enhanced ignition, from 121 ms to 107 ms at 0.1 MPa. More recently, our previous work^[9] measured ignition delay times of *n*-decane, cracking gas and cracked *n*-decane by using shock tube at 1296–1915 K, 0.1–0.2 MPa. $0.23\text{CH}_4/0.19\text{C}_2\text{H}_6/0.32\text{C}_2\text{H}_4/0.07\text{C}_3\text{H}_8/0.19\text{C}_3\text{H}_6$ (marked as cracking gas) was chosen as surrogate of cracking products of *n*-decane. Experiment results showed that *n*-decane and all these cracked *n*-decane ignited faster than cracking gas. Furthermore, cracked *n*-decane obtained at $T > 1480$ K for $x = 37.97\%$, 17.61% and at $T < 1480$ K for $x = 62.15\%$ showed shorter ignition delay time than *n*-decane, indicating that thermal cracking could improve ignitability with a limited degree. It should be noted that these studies only focus on surrogate of cracked fuel and very few calculated points for cracked fuels neglecting other complex components and free radicals of products. The complex free radicals produced by pyrolysis may influence the ignition process significantly for their active

characteristics. However, the complex diversity of products and the difficulty in capturing free radicals make it very difficult to measure the ignition delay time of cracked fuels. Therefore, it is necessary to investigate the ignition characteristics by theoretical simulation to make it clear about the effects of free radicals on ignition of cracked fuels.

Considering aviation kerosene is a complex mixture of different hydrocarbons^[10], it is necessary to use surrogate to simplify the problems^[9,11–12]. *n*-Decane has been used to be the surrogate of kerosene for its ignition delay time and properties similar to Jet fuels^[12–14]. Thus, *n*-decane was selected to study the ignition characteristics of cracked fuel in this work. Firstly, components of cracking products of *n*-decane are calculated at 3, 5 MPa and 945 K. Secondly, the ignition delay time for cracked *n*-decane based on cracking products were simulated at 300–1800 K, pressure of 0.1–3.0 MPa and equivalence ratio of 1.0. Thirdly, the further effects of pyrolysis conversions, pyrolysis pressures, ignition pressures and free radicals on ignition characteristics of cracked *n*-decane were investigated and analyzed.

2 Kinetic Model

Due to the difficulty to capture free radicals and the complexity of products, all the ignition calculations are based on calculated pyrolysis products of *n*-decane, consisting of gaseous and liquid products, and small amounts of free radicals. Some efforts were applied to develop pyrolysis mechanisms of *n*-decane applicable for different conditions in recent years. Ward et al.^[15] developed a unique two-dimensional computational fluid dynamics model to study the effects of pressure on flowing mild-cracked *n*-decane with low conversion. Malewicz et al.^[16] revised and extended the revised 1st Generation Surrogate model, basing on pyrolysis and oxidation of *n*-decane in the high-pressure single pulse shock tube. The additional revised mechanism showed improvements in predicting 1-olefin species profiles during the pyrolysis and oxidation of

n-decane. Jia et al.^[17] investigated *n*-decane pyrolysis under supercritical pressures (3–5 MPa) and developed *n*-decane pyrolysis mechanism containing 164 species and 842 reactions, which was validated by electrically heated tube test with products distributions and the chemical heat sink. Zeng et al.^[18] conducted pyrolysis experiments of *n*-decane in the flow reactor at 0.0007–0.1 MPa and developed a mechanism with 234 species and 1452 reactions. In this work, the mechanism proposed by Jia et al.^[17] was chosen as the basis of calculation for *n*-decane pyrolysis, because the validated experiments under the supercritical condition make it closer to real conditions in heat exchanger.

For oxidation mechanism of cracked *n*-decane, it is worth noting that the mechanism should perform good simulation for both light hydrocarbons and *n*-decane, since cracked fuels contain not only unreacted *n*-decane but also light hydrocarbons and some free radicals. Therefore, in current study, the reaction mechanism of cracked *n*-decane oxidation takes the merged mechanism (i.e. Combined mechanism) in our previous paper^[9], which was validated by predicting ignition delay time of both *n*-decane and light hydrocarbon (CH₄, C₂H₆, C₂H₄, C₃H₈, and C₃H₆) at 0.1 MPa.

The simulation of *n*-decane pyrolysis was performed using Plug Flow Reactor of Chemkin-pro package^[19], with measured axial temperature^[17]. The rationality of using one-dimensional homogeneous flow tube reactor has been verified in the Supporting Information. The calculations of ignition delay time of cracked *n*-decane were conducted in a closed homog-

enous batch reactor using Chemkin-pro package by assuming constant volume and adiabatic conditions. The ignition delay time τ_{ig} was defined as the time interval from the starting point of simulation to the maximum rate of temperature rise ($\max dT/dt$)^[4,20].

3 Results and Discussion

3.1 Pyrolysis Products Distribution of *n*-Decane

Calculation of pyrolysis of *n*-decane was performed by Chemkin-pro using the Plug Flow Code at 3–5 MPa (pyrolysis pressure marked as p_p), with outlet temperature of 945 K and a flow rate of 1.0 g·s⁻¹. The flow tube length is 1 m with internal diameter of 1.0 mm and the temperature distribution profiles along the reactor is taken from the measured data in literature^[17]. All the experimental data of *n*-decane pyrolysis were shown in Figure 1, including major gaseous and liquid species and the major free radicals in cracking products. The exiting conversions of pyrolysis of *n*-decane at 3 and 5 MPa reach to 46.2% and 58.8%, respectively. Figures 1a and 1b show more ethene and less alkane produced at 3 MPa than 5 MPa, consistent with the reported results in the literature^[15,21]. The behavior could be better understood by free radical chain reactions^[22], which describe that *n*-alkane chain firstly experiences decomposition by a carbon-carbon bond fission, following with bimolecular (H-abstraction reactions) or unimolecular reactions (β -scission reaction) to produce smaller alkane or alkene, respectively. Higher pressure is beneficial for bimolecular reaction rather than unimolecular reactions, result-

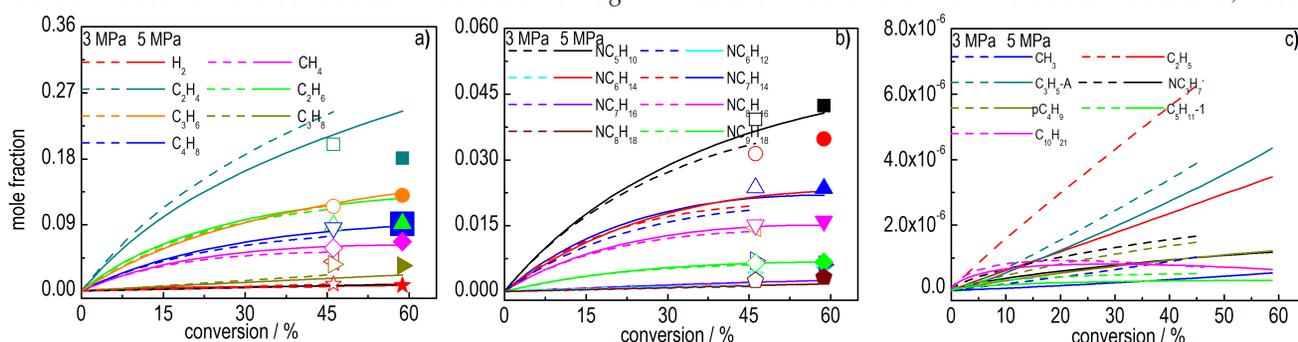

Fig.1 Simulated (lines) and experimental (dots)^[17] main products distributions of thermal cracking of *n*-decane at 3 MPa and 5 MPa. (a) main gaseous products; (b) main liquid products; (c) major free radicals

ing in more alkane production, while pressure decreasing is favorable to unimolecular reactions resulting in more alkene production.

Except stable molecular products, different kinds of free radicals were produced during the pyrolysis of *n*-decane. The seven initially produced free radicals (decyl contains all five different structures) are illustrated in Figure 1c. It can be observed that as the pressure increases, the contents of all free radicals decrease, especially for vinyl radical (C_2H_3). Although the content of free radicals is less about 4-5 orders of magnitude than stable pyrolysis products, the presence of free radicals maybe influence the ignition delay time of cracked *n*-decane significantly.

3.2 Ignition Delay Time of Cracked *n*-Decane

3.2.1 Effects of Pyrolysis Conversions of *n*-Decane

Figure 2 shows the ignition delay time of stoichiometric cracked *n*-decane over a range of temperature 1300–1800 K at 0.1 MPa (ignition pressure marked as p_i and *n*-decane conversion marked as x). It can be found that ignition delay times of these cracked *n*-decane are shorter than that of *n*-decane, indicating that thermal cracking could improve the ignitability. In addition, the promoting effect increases with the increasing of conversion of thermal cracking of *n*-decane. However, the results of cracked *n*-decane present large difference with experimental results in our previous work^[9], in which thermal cracking could improve the ignitability only at $T > 1480$ K for $x = 37.97\%$, 17.61% and at $T < 1480$ K for $x = 62.15\%$ to a limited degree. The main reason for the difference between experimental and theoretical results is that the components of pyrolysis products are different. In experimental research, only five lighter hydrocarbons ($0.23CH_4/0.19C_2H_6/0.32C_2H_4/0.07C_3H_8/0.19C_3H_6$) were proposed as the surrogate for pyrolysis products of *n*-decane, to simplify the problem and increase experimental operability. While in theoretical study, except the lighter hydrocarbons like methane, ethane, etc., the relative heavier pyrolysis products (i.e. liquid products) and a few free radicals are also considered. Furthermore, the different conditions of pyrolysis of *n*-decane in

both studies would lead to different products distributions, which is also accountable for the different results. Therefore, further experimental study on cracked fuels should be conducted based on more detailed components as surrogate of pyrolysis products.

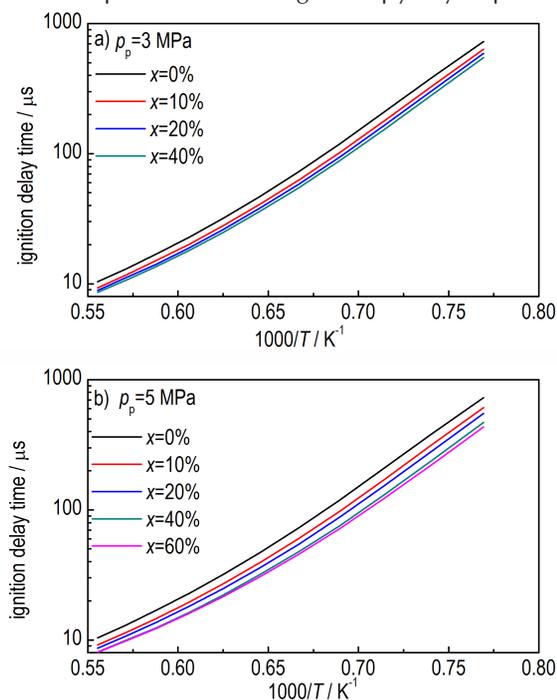

Fig.2 Predicted ignition delay times of cracked *n*-decane at different pyrolysis pressures with different conversions of *n*-decane

3.2.2 Effects of Pyrolysis Pressure of *n*-Decane

Different pyrolysis pressure might also influence the ignition delay time of cracked *n*-decane by affecting the products distribution. Figure 3 compares the ignition delay times at conversions of 10%, 20%, and 40% under pyrolysis pressure of 3 and 5 MPa. At the same cracking conversion, ignition delay time of cracked *n*-decane at 5 MPa is slightly shorter than that at 3 MPa, and with the deepening of the cracking, the difference of ignition delay time gradually increases. As indicated in section 3.1, pyrolysis products at 3 MPa have more ethylene and relative more free radicals, but the ignition is a little more difficult than that at 5 MPa. It can be concluded that ethylene content has no significant influence in the ignition of cracked *n*-decane, and the ignition delay time might be more relevant to the type of free radicals but not the content.

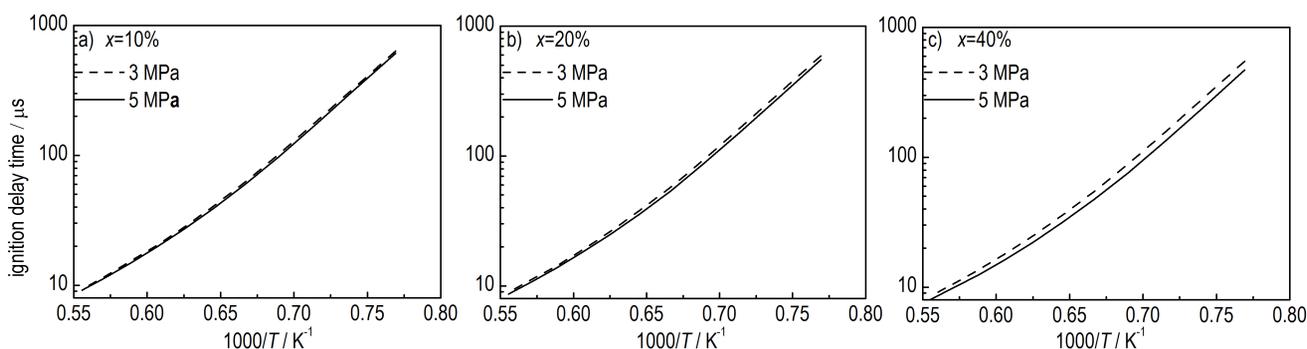

Fig.3 Predicted ignition delay times of cracked *n*-decane under different pressures at different conversions from 10% to 40%

Sensitivity analysis refers to the change of system characteristic quantity (such as ignition delay time) caused by the slight change of reaction rate constant of each chemical reaction under the condition of given temperature and pressure. Its value is called sensitivity coefficient, which can be calculated using equation (1). To better understand this result, sensitivity analysis was performed by perturbing the reaction rate constant by a factor of 2, using

$$S_i = \frac{\ln(\tau_+/\tau_-)}{\ln(k_+/k_-)} = \frac{\ln(\tau_+/\tau_-)}{\ln(2/0.5)} \quad (1)$$

Where S_i represents the sensitivity coefficient, k_+ and k_- represent the perturbation on reaction rate, τ_+ and τ_- represent the corresponding ignition delay time calculated with the increased and decreased rate coefficients, respectively. The positive coefficient indicates that the specified reaction inhibits the ignition, while negative indicates enhances ignition.

Figure 4 depicts the sensitivity analysis of ignition delay time of 40% cracked *n*-decane obtained under pyrolysis pressures of 3,5 MPa, at $p_i=0.1$ MPa, $T = 1500$ K, and $\varphi = 1.0$. It shows that the sensitive reactions for ignition of cracked *n*-decane are same and the mostly sensitive reactions are associated to C0—C3. It can be noted that R1: $\text{H} + \text{O}_2 = \text{OH} + \text{O}$ has the largest sensitivity coefficient to promote ignition because it is the most important chain branching reaction of hydrocarbons at high temperatures^[23–25]. Therefore, reactions producing H-atom have negative coefficients, such as R5 and R6, while those reactions consuming H-atom have positive coefficients, e.g. R25 and R26. Moreover, the formation of vinyl radical (C_2H_3) has a positive ef-

fect on ignition, such as the H-abstraction reaction of C_2H_4 by OH to form C_2H_3 (R3). The formed vinyl radical then reacts with oxygen, leading to another branching reaction (R4), resulting in positive improvement for ignition. In addition, the reaction producing resonance stabilized allyl radical ($\text{C}_3\text{H}_5\text{-A}$)^[26] and inactive methyl radical (CH_3) followed by chain termination reaction would inhibit the reactivity, such as R17, R27, and R21. Meanwhile, the chain termination reactions inhibit ignition by consuming active radicals to form stable structure, R14 and R26 for instance.

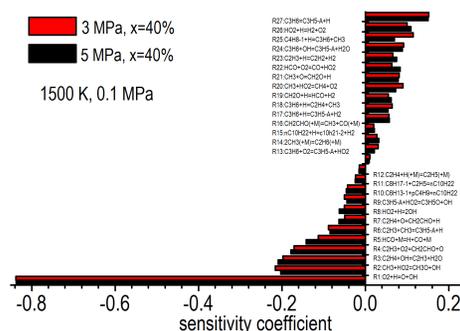

Fig.4 Sensitivity analysis for ignition delay times of two cracked *n*-decane under different pyrolysis pressures at 0.1 MPa, 1500 K, $\varphi=1$

The major free radicals (H, O, CH_3 , C_2H_5 , C_2H_3 , $\text{C}_3\text{H}_5\text{-A}$, etc.) mole fractions profiles are described in Figure 5, in which C_2H_5 , C_2H_3 molar fractions were enlarged five times for their low concentrations during the ignition process. As can be noted, the extremely sharp increases of H-atom and O-atom indicate the ignition of cracked fuel. Cracked *n*-decane at $p_p = 5$ MPa produces more vinyl radical (C_2H_3) and less methyl radical and allyl

radical (C_3H_5-A) than those at $p_p=3$ MPa.

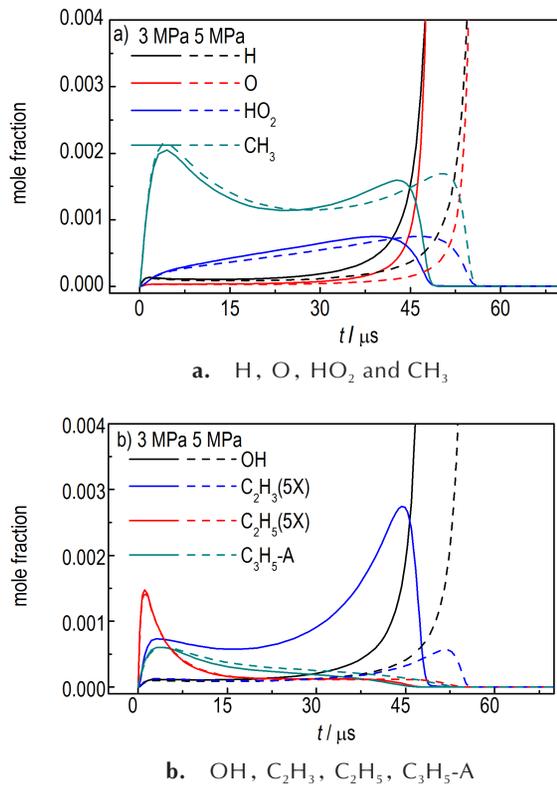

Fig. 5 At 1500 K, 0.1 MPa and $\phi=1$, predicted profiles of major radicals of two cracked *n*-decane under different pyrolysis pressure

3.2.3 Effect of Free Radicals in Pyrolysis Products

Free radicals could react with fuels directly by H-abstraction reactions, which might enhance the ignition progress by accelerating initial stage of fuel decomposition. Therefore, ignition delay time of cracked fuels with or without radicals were simulated at the temperature of 1300–1800 K and pressure of 0.1 MPa, as described in Figure 6. It can be noted that the ignition delay times of cracked *n*-decane with free radicals are shorter than that of cracked *n*-decane without radicals, and the ignition delay time become shorter with the conversions increasing.

For better understanding this result, Figure 7 ranks the sensitivity coefficients of stoichiometric cracked *n*-decane with or without free radicals in air of $p_p=5$ MPa, $x=40\%$, at $T=1500$ K, $\phi=1.0$ and 0.1 MPa. Consistent with section 3.2, most C0–C3 reactions are sensitive to cracked *n*-decane ignition, except R10 and R15. Similarly, chain branching re-

actions and reactions producing H-atom and C₂H₃ radical express negative sensitivity coefficients, while chain termination reactions, including reactions forming CH₃ and C₃H₅-A and consuming H atom show positive coefficients on ignition delay time.

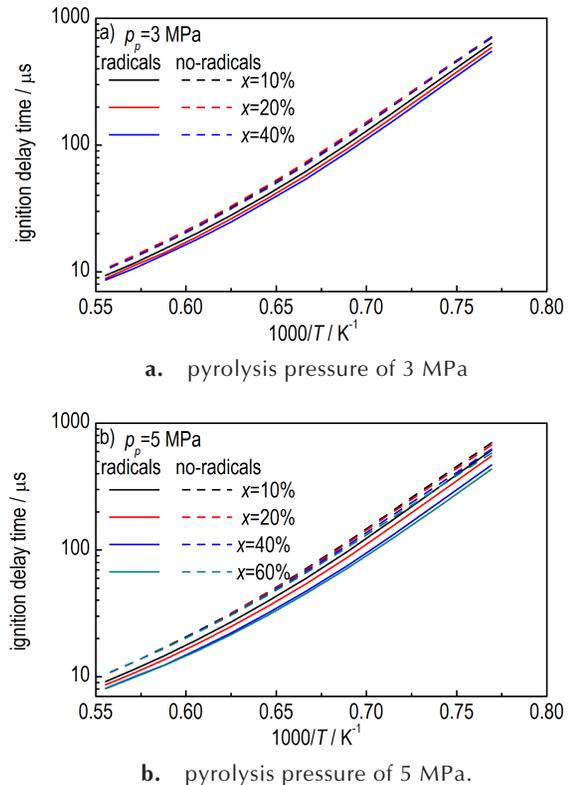

Fig. 6 Comparison for ignition delay times of two different cracked *n*-decane with or without radicals at 0.1 MPa, $\phi=1$. (a) pyrolysis pressure of 3 MPa, (b) pyrolysis pressure of 5 MPa

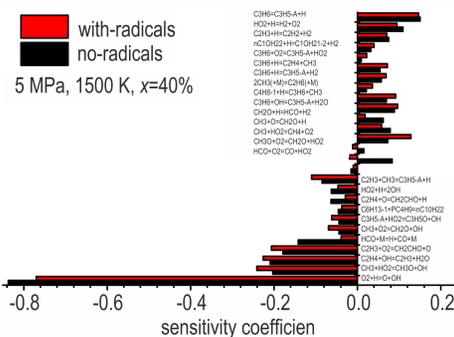

Fig. 7 Sensitivity analysis for ignition delay times of two cracked *n*-decane with or without radicals at 0.1 MPa, 1500 K, $\phi=1$

Similarly, the profiles of the major free radicals (H, O, CH₃, C₂H₃, C₂H₃, C₃H₅-A, etc.) are performed to analyze how the radicals change during

the ignition process, shown in Figure 8. As discussed in Section 3.2.2, the sudden increases of H-atom and O-atom indicate the ignition sign of cracked fuels. It also can be found that there has obvious difference of the amounts of major radicals between cracked *n*-decane with or without free radicals in air. Both less methyl radical and allyl radical (which would hinder the ignition process), along with more vinyl radical (C_2H_3) that helps the ignition, would result in shorter ignition delay time for cracked fuels with radicals.

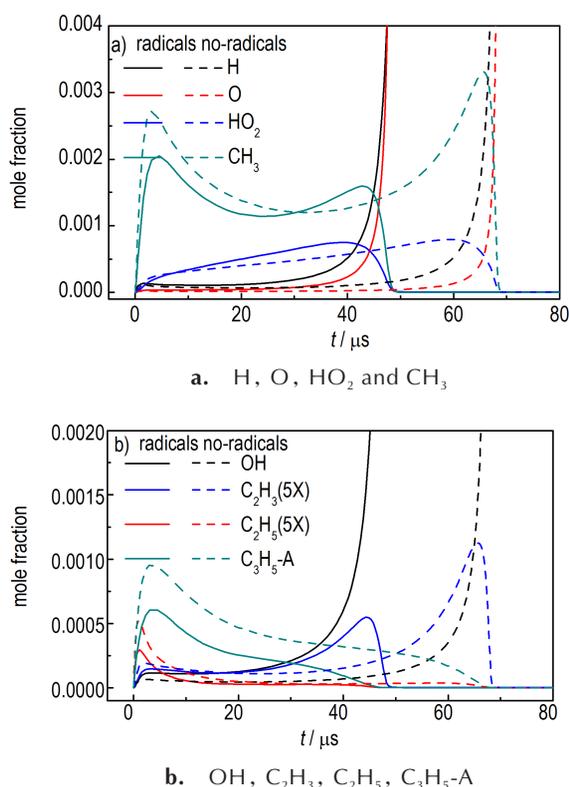

Fig. 8 Predicted profiles of major radicals of two cracked *n*-decane with or without radicals at 0.1 MPa, 1500 K, $\phi=1$

3.2.4 Effect of ignition pressures

The impact of ignition pressures on ignition delay times of cracked *n*-decane were also studied. Figure 9 shows the ignition delay time of cracked *n*-decane obtained under 5 MPa and $x = 40\%$ at temperatures from 1300 K to 1800 K, pressures from 0.1 MPa to 3.0 MPa. It could be noted that higher ignition pressures result in much shorter ignition delay times, resulting from higher concentration of fuels at higher pressures.

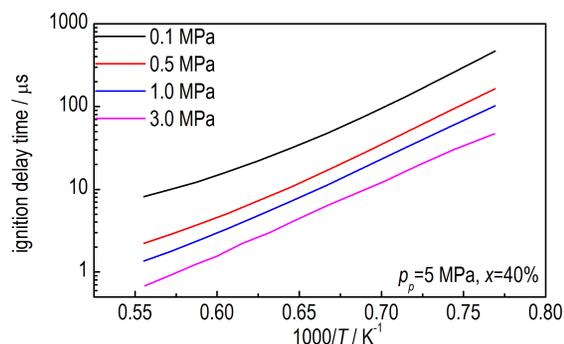

Fig. 9 Simulated ignition delay times of cracked *n*-decane under 5 MPa and $x = 40\%$ at different ignition pressures of 0.1–3.0 MPa

4 Conclusion

In advanced aircraft, endothermic hydrocarbon fuels firstly undergo thermal cracking to produce complex pyrolysis products and small amounts of free radicals prior to combustion. In this work, theoretical calculation was conducted to investigate the ignition delay time of cracked fuels (composed of unreacted fuels and pyrolysis products) by using *n*-decane as the surrogate of endothermic hydrocarbon fuels. The results showed the conversion rates of *n*-decane cracking at 3 and 5 MPa are 46.2% and 58.8%, respectively. The distribution of cracking products is consistent, but the ethylene content decreases with the increase of pressure, while the alkane content increases with the increase of pressure. Meanwhile, the content of free radicals at 3 MPa is slightly higher than that at 5 MPa, but the content of free radicals is very low. Ignition delay time increases with the decreasing of *n*-decane conversion and pyrolysis pressure, while higher ignition pressure can shorten it significantly. Furthermore, the presence of free radicals in cracked *n*-decane could accelerate the ignition process with ignition delay time shortening more than 15% when the conversion was less than 40%, compared with that of cracked *n*-decane without radicals. Sensitivity and rate of production analysis of major free radicals were conducted to try to analyze the above results, showing that most of sensitivity reactions are associated to C0–C3 reactions, and more vinyl radical (C_2H_3) and a little less

methyl radical and allyl radical (C_3H_5-A) formed during the ignition process could be helpful in the ignition stage of cracked *n*-decane.

Pyrolysis of fuels has a positive impact on ignition of cracked fuels in this theoretical work, exhibiting different results compared with experimental results. It is noteworthy that free radicals in cracked fuels display significant importance in ignitability of cracked fuels. Further efforts should be focused on experimental to study how radicals impact on the ignition delay time, to modify the mechanism and provide guidance for endothermic hydrocarbon fuels used in advanced aircraft.

摘要: 在先进飞行器发动机中, 吸热碳氢燃料在进入燃烧室之前会发生热裂解反应, 生成未反应燃料和小分子裂解产物的混合物(称为裂解态燃料)。本工作研究了在 1300~1800 K、0.1~3.0 MPa 和当量比为 1.0 的条件下, 不同的裂解转化率、裂解压力、点火压力和自由基对正癸烷裂解着火特性的影响。通过采用一种精确的组合机理, 从理论上计算了流动反应器中 3.0 和 5.0 MPa 下正癸烷裂解组分, 与文献中的实验结果吻合较好。结果表明, 正癸烷在 3 MPa 和 5 MPa 下裂解的出口转化率分别为 46.2% 和 58.8%, 裂解产物分布一致, 但乙烯的含量随着压力的升高明显的降低, 而烷烃含量随着压力的增大而增加。尽管自由基总体含量很低, 但在 3 MPa 条件下裂解产物中的自由基浓度依然高于 5 MPa 条件下。对于点火延迟时间的计算结果则表明, 裂解态正癸烷的点火延迟时间随着转化率的增大而延长, 且在 5 MPa 下随着转化率的变化更明显。相同转化率下, 5 MPa 下的裂解态正癸烷的点火延迟时间比 3 MPa 下更短。此外, 与无自由基的裂解正癸烷相比, 裂解正癸烷中自由基的存在可以加速着火过程, 转化率小于 40% 时, 着火延迟时间缩短 15% 以上。
